1. Introduction

The distinction between syntactic and semantic techniques in linguistic theory is by now sufficiently clear. What is often debated is the extent to which syntactic and semantic considerations should be used in analyzing a given phenomenon. An empirical domain where the division of labour between syntax and semantics is especially problematic is the case of “non-overt” scope, or what I prefer to call the *scopal semantics* of various constructions. One way to approach the problem has been to study the *asymmetries* in the scopal behaviour of different expressions. For instance, Reinhart (1997) considers the free scopal properties of indefinite noun phrases as opposed to the island-restricted scope of other NPs. This asymmetry is used to argue for a novel semantic account of the scope of indefinites, in addition to a traditional syntactic operation of Quantifier Raising that applies to noun phrases generally.

This paper uses a similar line of reasoning for analyzing some scopal asymmetries with coordination. As in Winter (1995), I propose that scopal peculiarities in the interpretation of *and* follow from a semantic peculiarity: this coordinator has no lexical meaning and its standard boolean contribution to sentence meaning is carried out by a (universal) grammatical operation. As for *disjunction*, I adopt the proposal in Larson (1985) that wide scope interpretations of *or* result from a syntactic process that also controls the overt distribution of *either...or* coordinations. I support Larson’s proposal by considering some data that refute the hypothesis in Winter (1995) that wide scope *or* phenomena are restricted to intensional contexts. The semantic mechanism for interpreting *and* coordinations is also used in a natural way for structures that are generated by a variation on Larson’s syntactic procedure. Thus, while scopal asymmetries between conjunction and disjunction are reflected in syntactic and lexical differences between the two constructions, the compositional semantics of both kinds of coordination is given a unitary treatment.

* I thank the participants of the conference on Interface Strategies, and especially Edit Doron, Shalom Lappin, Alice ter Meulen and Tanya Reinhart, for their remarks. I am also grateful to an anonymous reviewer for many useful comments on style and content.
Section 2 briefly reviews some basic principles of the boolean semantics of coordination, which is the point of departure for the semantic analysis in this paper. The treatment in Winter (1995) of wide scope *and* phenomena is summarized in Section 3. Section 4 deals with wide scope *or* and argues for a variation on the syntactic proposal in Larson (1985), which combines naturally with the proposed semantics of wide scope *and*. By way of discussing two previous semantic proposals for treating the scope of coordination, Section 5 recapitulates some data and discusses a remaining problem.

2. The semantic point of departure: boolean coordination

Any treatment of scope phenomena needs to start from minimally controversial hypotheses concerning the interpretation process. Probably the most significant fact about the syntax-semantics of coordination is its *cross-categorial* nature: coordinators like *and* and *or* apply to different syntactic categories of different semantic types. A few elementary examples are given in (1).

(1)  
   a. Mary sang and/or danced.  
   b. Mary and/or Sue sang.  
   c. Mary sang and/or Sue danced.

The immediate semantic question that this cross-categorial behaviour raises is how one denotation of the coordinator is able to combine with different category meanings.

The traditional answer to this question provided by Transformational Grammar was to deny that coordinators are semantically cross-categorial to begin with: at Deep Structure coordinations were viewed as only sentential, as in standard first order logics. To uphold this assumption, a syntactic rule of *Conjunction Reduction* was postulated. This transformation relates surface forms of non-sentential coordinations as in (1a–b) to Deep Structures as in (2a–b) with sentential coordinations.

(2)  
   a. Mary sang and/or Mary danced.  
   b. Mary sang and/or Sue sang.

There are obvious methodological objections to this line of analysis. Any postulation of such complicated syntactic operations should have convincing motivation. Conjunction Reduction was motivated mainly by the metaphysical preference for first order logic as a representational level for natural language semantics.

Empirically speaking, applications of Conjunction Reduction as (roughly) illustrated in the transition from (1a–b) to (2a–b) seemed tenable only because the basic semantic properties of quantificational expressions were not taken into account. For instance, sentences (3a) and (3b) are obviously not equivalent. However, (3b) is the only Deep Structure assumed for (3a) by standard views on Conjunction Reduction. Hence, the rule incorrectly predicts that the two sentences are semantically equivalent.

(3)  
   a. Exactly one girl sang and danced.  
   b. Exactly one girl sang and exactly one girl danced.
There are many noun phrases that do not give rise to the equivalences expected under the Conjunction Reduction analysis. In (4) I summarize additional cases where the expected equivalence does not appear with *and/or* VP coordinations. Some cases where equivalences do appear are given in (5).

(4)  
a. NP sang and danced ⇔ NP sang and NP danced  
    NP = some girl, no girl, not every girl, Mary or Sue, at least/most five girls, 
    exactly five girls, most girls  
b. NP sang or danced ⇔ NP sang or NP danced  
    NP = every girl, no girl, not every girl, Mary and Sue, at least/most five girls, 
    exactly five girls, most girls

(5)  
a. NP sang and danced ⇔ NP sang and NP danced  
    NP = every girl, Mary, Mary and Sue  
b. NP sang or danced ⇔ NP sang or NP danced  
    NP = some girl, Mary, Mary or Sue

These patterns are not explained by traditional Conjunction Reduction.

The modern semantic analysis of coordination, developed most thoroughly in Keenan and Faltz (1985), starts with the simple assumption that the input to the semantic component involves the constituents as coordinated at surface structure. In particular, no syntactic rule like Conjunction Reduction is stipulated. Second, Keenan and Faltz put forth the hypothesis that the semantics of coordination is boolean: the coordinators *and* and *or* denote the *meet* and *join* operators of boolean algebras. Simplifying a bit, this means that *and* is interpreted as set intersection while *or* denotes set union. In the special case of coordination at the sentence level, the boolean operators boil down to the standard propositional operators on truth values. This treatment gives a highly elegant cross-categorial account of coordination. For instance, the semantic analysis of predicate coordination as in (1a) is analogous to the analysis of NP coordination in (1b): in both cases the conjunction/disjunction denotes set intersection/union respectively. In (1a) the analysis of the predicates as sets is straightforward. In (1b), the standard Generalized Quantifier analysis of noun phrases takes them to denote sets of sets, to which the boolean operators apply. In general, the combination of the boolean treatment of coordination with standard generalized quantifier theory directly predicts the patterns observed above in (4) and (5). I omit here a detailed illustration of this familiar analysis. Just to give a flavor of its simplicity, consider the different behaviour of the determiner *every* with respect to VP conjunction and disjunction: sentence (6a) is equivalent to (6b), whereas (7a) is not equivalent to (7b). This is directly accounted for by the basic assumptions on coordination and generalized quantifiers, as illustrated below using standard set-theoretical notation. The boldface symbols stand for the set denotations of the respective noun or verb.

(6)  
a. Every girl sang and danced.  
    sing' ∩ dance' ∈ {a: girl' ⊆ a}  
    ⇔ girl' ⊆ sing' ∩ dance'  
    ⇔ girl' ⊆ sing' ∧ girl' ⊆ dance'
b. Every girl sang and every girl danced.

\[
\text{sing}' \in \{A: \text{girl}' \subseteq A\} \land \text{dance}' \in \{A: \text{girl}' \subseteq A\} \\
\Rightarrow \text{girl}' \subseteq \text{sing}' \land \text{girl}' \subseteq \text{dance}'
\]

(7) a. Every girl sang or danced.

\[
\text{sing}' \cup \text{dance}' \in \{A: \text{girl}' \subseteq A\} \\
\Rightarrow \text{girl}' \subseteq \text{sing}' \lor \text{girl}' \subseteq \text{dance}'
\]

b. Every girl sang or every girl danced.

\[
\text{sing}' \in \{A: \text{girl}' \subseteq A\} \lor \text{dance}' \in \{A: \text{girl}' \subseteq A\} \\
\Rightarrow \text{girl}' \subseteq \text{sing}' \lor \text{girl}' \subseteq \text{dance}'
\]

Note that the contrast between the equivalence (6a) \(\Leftrightarrow\) (6b) and the non-equivalence (7a) \(\Leftrightarrow\) (7b) is accounted for using a simple set-theoretical property: when the intersection of two sets sing' and dance' contains a set girl', then both intersected sets contain girl' independently. By contrast, when the union of these two sets contains the set girl' we cannot infer that either set in isolation contains the set girl'.

Similar distinctions easily account for the other (non-)equivalences in (4) and (5) above. What may seem at first glance to be a complex pattern of scopal asymmetry between and and or with respect to their interactions with various NPs is accounted for as a logically trivial distinction between the boolean meanings of conjunction and disjunction. I consider this to be the best possible account of "scopai" asymmetries. However, the main argument of this paper is that this line of theorizing, although correct, is unfortunately still incomplete: other scopal asymmetries between conjunction and disjunction call for a more intricate division of labour between syntax and semantics in the analysis of coordination.

3. Wide scope and

One kind of examples that is not amenable to a straightforward boolean account of coordination was pointed out by Bergmann (1982) (among others).

(8) Every man and woman arrived.

Under the boolean analysis of (8) the two sets denoted by the nouns man and woman are first intersected and their intersection is the argument of the determiner every. This leads to a strange interpretation of (8) claiming that every entity that is both a man and a woman arrived. However, the sentence has a completely reasonable interpretation, equivalent to the sentence every man and every woman arrived.

This fact does not imply that a simple boolean analysis of sentences like (8) is wrong, but it does imply that the boolean analysis is insufficient. In fact, other sentences of the same form show that we are facing a case of ambiguity here. For instance, sentence (9) below can be true in case every linguist and every philosopher knows Gödel's Theorem. However, the sentence can also be asserted in case some linguists or some philosophers do not know Gödel's Theorem, as long as all the people who are experts in both
disciplines know it. This means that the "boolean reading" is still motivated for sentences like (9), while in (8) it is reasonably obviated by pragmatic factors; to wit, the reference to androgynes made in this reading, which is unlikely in the absence of an appropriate context. We may refer to the compositionally derived reading of (9), formalized in (9a), as the narrow scope (NS) reading of and relative to every. Under the other reading, formalized in (9b), we say that the coordinator and takes wide scope (WS) over the determiner every.

(9) Every linguist and philosopher knows Gödel’s Theorem.
   a. NS: (every'(linguist' ∩ philosopher'))(know_gödel')
   b. WS: (every'(linguist') ∩ every'(philosopher'))(know_gödel')

As summarized in Winter (1995), there are additional constructions where and shows wide scope behaviour that is not expected under a simple boolean theory. Some of these examples are repeated below, with the paraphrase of the WS and reading.

(10) a. Mozart is easy to play for every pianist over 60 and below 20.
    WS: “Mozart is easy to play for every pianist over 60 and for every pianist below 20”.
   b. Every too tall and too short person suffers from this symptom.
    WS: “Every too tall person and every too short person suffers from this symptom”.

(11) John sold and bought a car.
    WS: “John sold a car and bought a car”.

(12) (A woman discovered Radium but) a man invented the electric light bulb and developed the theory of relativity. (after Hendriks 1993)
    WS: “A man invented the electric light bulb and a man developed the theory of relativity”.

(13) The bird is some small distance above the house and below the cloud.
    WS: “The bird is some small distance above the house and some small distance below the cloud”.

1 Edit Doron (p.c.) suggests that for “episodic” verbs like arrived or played basketball substituted in (9), the NS reading is completely unavailable. I do not know how robust these intuitions are across speakers, nor do I know of any possible explanation. A reviewer of this paper points out the following example: the physicist and amateur violinist that you invited has just arrived. This goes against Doron’s intuition, because the subject of this sentence can be analyzed using NS coordination (taking about a physicist who is also an amateur violinist). However, I was not able to construct such examples with the determiner every. Note that matters are highly complicated if Doron’s intuition turns out to be correct and NS readings turn out to be unavailable for and coordinations in some cases. This is because, as I show below, only NS readings are available for or in parallel constructions.

2 See Zwarts and Winter (1997) for the semantics of such cases of PP modification.
Note that these examples require some reconsideration of the description of the facts assumed in Section 2. Now we see that some sentences with coordination have readings that are expected by the Conjunction Reduction analysis and are unexpected by a straightforward version of the boolean analysis. However, these “wide scope” readings are clearly special. First, as will be argued later in this paper, some syntactic configurations allow WS interpretations for and coordinations but not for or coordinations. This is unexpected by the Conjunction Reduction analysis. Second, WS interpretations of coordination are additional to the NS interpretations derived by the boolean analysis. The NS readings are also available in the presence of WS readings, which is a fact that no straightforward Conjunction Reduction analysis expects. Thirdly, most cases of WS coordination involve some pragmatically special situations that reduce the plausibility of the NS interpretation. For instance, consider sentence (11) above. The NS reading of this sentence states that there is a car that John both sold and bought. Under this reading, the linear order of the verb conjuncts would suggest that John sold one car and bought again the same car, which is an unlikely situation. In this case, where the NS reading is so unlikely to be true, the WS reading suddenly appears. By contrast, Partee and Rooth (1983) correctly argue that sentence (14) below strongly suggests that John caught a fish that he caught. The sentence does not easily allow a situation in which John caught one fish and ate another one, as a WS and analysis would allow.

(14) John caught and ate a fish.

Many such sentences, where the NS reading describes a plausible situation, often do not show any WS coordination effect.

These points suggest that while some additional mechanism(s) on top of the boolean analysis are certainly needed in order to account for WS interpretations of coordination, these mechanisms are somewhat peripheral. In this paper I will concentrate on constructions where WS interpretations of and and or are clear due to contextual or pragmatic factors and I will not try to explain why they are often missing or highly marked in similar constructions with different lexical content (cf. (11) vs. (14)). Reasonably, an explanation of such facts could be that WS interpretations of coordination are somewhat “costly” and they therefore appear in circumstances where there is clear pragmatic motivation not to use the NS interpretation.

The WS readings paraphrased above cannot be generated by the boolean denotation of and without introducing further complications in the syntactic/semantic machinery. In Winter (1995) I introduced an additional assumption about the semantics of and that made it possible to generate the missing readings. According to that proposal, the cooperator and does not have a meaning of its own. Binary conjunctions with and only result in a concatenation of the meanings of the conjuncts as an ordered pair of denotations. In the more general case, two or more conjuncts form an n-tuple of denotations, or a “structured meaning”. Thus, in a sentence like (9), the denotations of the noun conjuncts are “amalgamated” as the pair <linguist, philosopher>. From this stage on, there are two possibilities. First, since and does not lexically convey set intersection, something else has to provide this meaning. I proposed that intersection is a universal semantic operation that can freely apply to any tuple of meanings generated
by the grammar. This strategy immediately gives us the narrow scope reading of (9): intersection is basically an operation on tuples, as illustrated by the notation in (15).

\[ \cap <\text{linguist'}, \text{philosopher'}> = \text{linguist'} \cap \text{philosopher'} \]

The alternative strategy is to let the pair be the direct argument of the determiner every without first intersecting its members. Under this construal, we let the determiner every apply to the two conjuncts pointwise. This means that instead of applying to one argument at a time, every can apply to each argument separately. This procedure is formally defined in (16).\(^3\) The result of the operation is a tuple that consists of the two quantifiers every'(<linguist'>) and every'(philosopher'). Application of intersection to this pair derives the wide scope reading of the conjunction, as demonstrated in (17).

\[ \begin{align*}
\text{(16)} & \quad \text{Pointwise application: Let } f: A \to B \text{ be a function and } <x, y> \text{ be a tuple s.t. } x \in A \\
& \quad \text{ and } y \in A. \text{ We define: } \\
& \quad f(<x, y>) = <f(x), f(y)> \\
\text{(17)} & \quad \text{every}'(<\text{linguist'}, \text{philosopher'}>) \\
& \quad \text{ by pointwise application we derive: } \\
& \quad <\text{every}'(\text{linguist'}), \text{every}'(\text{philosopher'})> \\
& \quad \text{by free application of intersection: } \\
& \quad \text{every}'(\text{linguist'}) \cap \text{every}'(\text{philosopher'})
\end{align*} \]

This procedure distinguishes and from or: while and, due to its zero meaning, can give rise to WS readings as illustrated in (17), the same process cannot apply with or without further assumptions. Since or lexically conveys boolean join, its denotation standardly applies to the conjuncts. Hence, the disjunction itself cannot have any tuple denotation. As we shall see below, this distinction between and and or has welcome consequences for the analysis of the scopal asymmetries between the two coordinators. In Winter (1995) I propose that the above assumptions are also useful in accounting for two other asymmetries between conjunction and disjunction. One asymmetry concerns the interpretation of alternately adverbials. As pointed out by Lasersohn (1992), sentences like (18) cannot be interpreted correctly if and denotes the standard boolean function. The reason is that the intersection of the set of hot entities and the set of cold entities at a given point of time is reasonably the empty set. This makes further temporal modification using alternately problematic.

\[ \text{(18)} \quad \text{John was alternately hot and cold.} \]

To analyze the sentence under the present assumption, we stipulate that the denotation of alternately is a function that takes a tuple as an argument. This analysis prevents any application of intersection in (18) because the intersected denotation is no longer a tuple, hence not a suitable argument for alternately. The temporal semantics of the sentence is easily accounted for using a proper definition of alternately as proposed in Winter.

\(^3\) In Winter (1995) a more general mode of operation is defined for tuples to allow treatment of more complex constructions with coordination.
(1995). This also explains why alternately cannot appear with or coordinations as in (19): since or does not allow tuple formation, the denotation of the disjunction simply does not have the right type for an argument of alternately.

(19) *John was alternately hot or cold.

Another difference between conjunction and disjunction is the possibility that exists in many languages to omit a conjunctive morpheme. For instance, the Pacoh sentence (20), from Payne (1985), does not have any clear parallel to the and in the English translation. The Turkish sentence (21), also from Payne (1985), exemplifies a more common strategy of languages that do have a conjunctive morpheme but allow it to be omitted without change of meaning. Similar phenomena with disjunctive coordinators do not seem to appear in any language.

(20) do [\text{\textit{vi}}p, \text{chö tőq cayaq chö tőq apây}]  
she return to husband return to grandmother  
“She returns to (her) husband and returns to (her) grandmother”

(21) [\text{\textit{ni}}p, \text{sen, ben, vel/\textit{\theta} kardeçin}]  
you, I and/\textit{\theta} brother-your  
“you, I and your brother”

This zero strategy with conjunction is expected under the present view: since the conjunctive morpheme is devoid of any denotation of its own and intersection is performed by the grammar, languages can also express logical conjunction in the absence of a coordinator morpheme. The same does not hold of the disjunctive morpheme, which must be present in order for a coordination to express boolean join.

4. Wide Scope or

As mentioned above, the proposed semantic process makes no immediate predictions concerning a possible “non-overt” scope for disjunction. Such effects do exist, however. Since Rooth and Partee (1982), attention has been paid to cases where truth-conditions of disjunctions are not easily derived by the boolean treatment of or. Rooth and Partee’s famous example is repeated below.

(22) Mary is looking for a maid or a cook.

The classical Montagovian analysis assigns (22) a de dicto reading, under which the sentence does not require that either maids or cooks exist. The reading claims that Mary will be satisfied if she finds any maid, and she will be satisfied as well if she finds any cook. However, Rooth and Partee recognize another de dicto reading of (22), which is

\footnote{The absence of an existence requirement can be easily verified by replacing the nouns maid or cook in Rooth and Partee’s original example by more plausible candidates for non-existence like unicorn or angel.}
problematic for the standard Montagovian analysis. Sentence (22) can be uttered truthfully in case Mary is in fact looking for a maid and she is not interested at all in finding a cook, or, conversely, in case Mary’s interest is not in finding any maid but rather in finding a cook. This interpretation of (22) is equivalent to the sentence *Mary is looking for a maid or looking for a cook*. Under this reading the sentence expresses uncertainty as to Mary’s preferences. The uncertainty implication can be strengthened by expressing (22) with an addition like “but I don’t know whether it is a maid or a cook that Mary is looking for”. We refer to this interpretation of (22) as its (de dicto) wide scope or reading. Note that sentences like (22) have an independent de re interpretation, which does assert the existence of maids or cooks. Under this reading (22) claims that there is a particular maid or a particular cook for whom Mary is looking. This reading is irrelevant for our purposes.

Larson (1985) observes that the availability of a WS or reading correlates with the position of *either* in *either...or* constructions. When *either* appears adjacent to the *or* coordination as in (23) the sentence can have both de dicto readings as in sentence (22). By contrast, when *either* appears “displaced” from the *or* coordination as in (24a–c), we get only the wide scope or reading: according to Larson, these sentences must be interpreted as expressing uncertainty with respect to Mary’s interest.

(23) Mary is looking for *either* a maid or a cook.
(24) a. *Either* Mary is looking for a maid or a cook.
    b. Mary *either* is looking for a maid or a cook.
    c. Mary is *either* looking for a maid or a cook.

Larson further argues that the “covert” scope of *or* is confined to those positions where *either* can appear overtly. For instance, the sentences in (25a–b), with a negation particle in the scope of *either*, are considered ungrammatical or at best marginal. Correspondingly, sentence (26) does not have any clear WS or reading beyond the negation as paraphrased in (27).

(25) a. *?Either* Mary isn’t looking for a maid or a cook.
    b. *?Mary either* isn’t looking for a maid or a cook.
(26) Mary isn’t looking for (either) a maid or a cook.
(27) “Mary isn’t looking for a maid or isn’t looking for a cook” (unavailable interpretation).

Larson’s general statement of these facts is summarized below.

(28) **Larson’s generalization:**

a. In *or* coordinations without *either*, as well as in *either...or* coordinations with *either* undisplaced: the scope of *or* is confined to those positions where *either* can potentially appear.

b. When *either* is displaced it specifies the scope of *or* to be at that displaced position.
Before moving on to a possible account of these facts, there are some empirical points that call for elaboration. As mentioned in Winter (1995), the literature has concentrated on the behaviour of disjunction scope only in intensional contexts as in the above sentences. I proposed that in fact, intensionality is necessary for WS or effects to appear. If this claim is correct, it goes against any account of WS or that does not appeal to the semantics of intensionality. However, I would like to show now that this argument was wrong: wide scope or can also appear in extensional contexts, but its distribution is restricted as anticipated by Larson’s generalization. Consider first sentence (29) below, the disjunctive variation of (9). Unlike the conjunction in (9), the disjunction in sentence (29) does not seem to have a wide scope interpretation as paraphrased in (30): sentence (29), like its narrow scope interpretation, and unlike (30), requires that all the linguists and all the philosophers know Gödel’s Theorem. Incidentally, this is just the wide scope reading of and in sentence (9).

(29) Every linguist or philosopher knows Gödel’s Theorem.
(30) Every linguist or every philosopher knows Gödel’s Theorem.

In order to account for the apparent absence of a WS interpretation for the coordination in sentence (29) (vis à vis (9)) we might try the following line of explanation. Suppose that sentence (29) does in fact have a WS reading for or as paraphrased in (30). However, this reading is “masked” by the NS reading of the coordination in the absence of any pragmatic factors that would make it more accessible than the NS reading. I think this approach to the analysis of (29) is a priori plausible. However, I will now show it to be unfounded. The idea is to find a context where the NS reading of (29) is highly unsuitable while the (putative) WS reading is still acceptable. If the approach just described is on the right track, we expect sentences like (29) in such a context to exhibit a clear WS effect. The following example shows that this expectation is not borne out.

Consider the following context: a doctor examined all the boys and all the girls in some class and she has left a list with a +/- sign against the name of each child. The sign indicates whether the child should be further examined or not. Unfortunately, we don’t know if the doctor intended + to mean “the child is perfectly healthy” or to mean “the child should be further examined”. However, we do discover that all the boys got a + whereas all the girls got a -. We therefore conclude that:

(31) #Every boy or girl should be further examined.

Sentence (31) is clearly unsuitable in the given context. Like sentence (32) it is falsified by our knowledge that either the boys or the girls are perfectly healthy. By contrast, under the same context sentence (33) is completely suitable.

(32) #Every boy and every girl should be further examined.
(33) Every boy or every girl should be further examined.

5 A similar fact was observed in Bergmann (1982).
Sentence (32) unambiguously paraphrases the narrow scope reading of (31). Sentence (33) expresses the putative WS or reading of (31) that is under examination here. If a WS or reading was grammatically available for sentence (31), we should have expected (31) to be suitable just like sentence (33). That this is not the case supports our claim that sentence (31) is in fact unambiguous: its unacceptability in the given context is expected by the assumption that it only has the NS or reading equivalent to (32), which is equally unacceptable in this context.

Once we conclude that coordinations as in (31) are not scopally ambiguous, we have to explain the contrast between such cases and the scopal ambiguity of or in sentences like (22) above (= Mary is looking for a maid or a cook). In Winter (1995) I argued that this contrast indicates that WS effects with or are intimately related to the intensionality of expressions like look for. However, the unavailability of WS or in (31) is also completely in line with Larson's syntactic observation: it is compatible with the ungrammaticality of (34), where either marks a disjunction scope over the determiner.

(34) *Either every boy or girl should be further examined.

Thus, the question about the origins of WS or in (22) is still undecided: it may result either from intensionality mechanisms or from Larson's syntactic assumptions. I would like to show now that Larson's syntactic account is more likely to be the origin of WS or than an intensionality based account. Consider the following sentence.

(35) Every man over 30 or over 40 suffers from this symptom.
   a. “every man over 30 or over 40 suffers from this symptom”
      = \( \text{every'(man' } \land (\text{over}_{30'} \cup \text{over}_{40'}))\text{(suffer')} \)
      \( \Leftrightarrow (\text{every'(man' } \land \text{over}_{30'}))\text{(suffer')} \)
   b. “every man over 30 or over 40 suffers from this symptom”
      = \( (\text{every'(man' } \land \text{over}_{30'})) \cup (\text{every'(man' } \land \text{over}_{40'}))\text{(suffer')} \)
      \( \Leftrightarrow (\text{every'(man' } \land \text{over}_{40'}))\text{(suffer')} \)

The narrow scope or reading of (35) as formalized in (35a) is equivalent to the claim that every man over 30 suffers from the symptom. This occurs because the set of men over 40 is a subset of the set of men over 30, hence their union is the set of men over 30. This NS reading in (35a) is of course stronger than what (35) actually asserts. By contrast, if we assume that sentence (35) has the wide scope or reading in (35b), we analyze the sentence as equivalent to the claim that every man over 40 suffers from the symptom. I would like to argue that this is the prominent reading of (35). Of course, (35b) is a bit weaker than what (35) implies in actual discourse: the sentence implicates that there is a possibility that also men between 30 and 40 suffer from the symptom. This implication, however, is reasonably a Gricean conversational implicature that comes from the use of the disjunct over 30: a speaker that does not want the utterance of (35) to imply the possibility that men between 30 and 40 also suffer from the symptom had better be more concise and just use the single conjunct over 40 instead the coordination in (35). To sum up, in the case of (35) it is clear that the sentence cannot assert the NS or reading in normal situations. The WS or reading is here a natural candidate for its interpretation. This is an example that goes against my claim in Winter (1995) that WS
or phenomena depend on intensionality: no expression in (35) can be argued to be “more intensional” than the cases of WS and considered in Section 3.

Moreover, (35) gives further support to Larson’s generalization: consider sentence (36), which does (marginally) allow introduction of either at a position that corresponds to the WS interpretation of or.

(36) Either every man over 30 or over 40 suffers from this symptom.

The contrast in grammaticality between (34) and (36) vis-à-vis the contrast in the WS or interpretation between (31) and (35) is expected under Larson’s generalization.

An additional piece of evidence for Larson’s generalization is the contrast between the availability of WS or in (35) and its unavailability in the following sentence.

(37) Every woman or mother suffers from this symptom.

Although in both (35) and (37) a set and its superset are coordinated by or, which makes the NS reading pragmatically odd, it is only in (35) that a WS or reading appears. Sentence (37), by contrast, does not assert that every mother suffers from this symptom, although this is the truth-conditional content of the WS or reading: every woman or every mother suffers from this symptom. Rather, the sentence conveys only the NS or reading, which claims that every woman suffers from this symptom. Thus, the oddness of (37) reasonably appears due to the redundancy of the mother conjunct. If a WS or reading existed in this sentence we should have expected it to be as salient as in (35). The absence of this WS or interpretation further supports Larson’s observation because either could not be prefixed to sentence (37).

After we have also supported Larson’s generalization with respect to extensional contexts, we may move on to its account. Larson proposes that in disjunctions without any overt either particle there is a null element he labels O, which functions like an overt either. In Larson’s account, both either and O can optionally move at LF to any of the positions where either is realized at surface structure. This LF position of either/O determines the scope of the disjunction. The case of displaced either as in (24) is special in that no further movement of either at LF is possible since it has moved already at surface structure.6

Larson proposes to interpret the structures generated by his assumptions using the semantic mechanism of Rooth and Partee (1982) (see Section 5). I would like to propose a modification of Larson’s assumptions that will allow us to simplify the semantic

---

6 Larson justifies this last assumption by the following familiar similar observation on wh elements. A coherent answer to the question in (i) is: Mary knows that John bought a house. By contrast, this is not a possible answer to (ii). In LF terminology this is described by saying that the what NP in (ii) cannot move further at LF since it is already displaced at surface structure. By contrast, in (i) what is in situ and consequently it can move at LF to give rise to a question asking about pairs of people and the things they know that John bought.

(i) Who knows that John bought what?
(ii) Who knows what John bought?
mechanism for WS or and to unify it with the account of WS and from Section 3. Tanya Reinhart (p.c.) suggests that instead of assuming a null O item in disjunctions, we may assume movement of or itself. First, assume that any overt position of either is a position to which or can optionally move at LF, after adjunction to the coordination node. When either is present, movement of or to the position of either is obligatory. When either is undisplaced, further movement of either...or from this position is optional as in plain or coordinations. When either is displaced, no further movement of either...or is allowed. These three cases of plain or, undisplaced either and displaced either are summarized in figures 1, 2 and 3 respectively.

Figure 1. Plain or.

Figure 2. either undisplaced.

Figure 3. either displaced.
These assumptions reflect Larson’s generalization in a way similar to Larson’s own proposal. Semantically, the structures generated by these revised assumptions can be easily interpreted using the mechanism of Section 3: note that after or movement the remaining material in the coordination can be interpreted like any and coordination — since there is no function that coordinates the denotations of the conjuncts, the only available option is tuple formation. Unlike the case of conjunction, with disjunction a coordinator denotation is present but at a higher compositional level than the coordination itself. Pointwise application is the mechanism responsible for carrying the semantic computation with tuples to this level, where the resulting tuple is “discharged” by the or coordinator. This semantic analysis is illustrated in Figure 4 by way of analyzing the WS or reading of sentence (22).

The syntactic analysis of this reading of (22) involves movement of or over the predicate looking for. The coordination a maid or a cook is therefore left at LF with no coordinating semantic material. This is analogous to the situation with and conjunction and hence the pair <a_maid’, a_cook’> is formed, to which the verb can apply pointwise. The resulting pair is:

<look_for’(a_maid’). look_for’(a_cook’), a_maid’ a_cook’>

This is the input to the join denotation of or, which results in the correct WS interpretation. Recapitulating the proposal, we adopt one crucial distinction between conjunction and disjunction that is used in accounting for the scopal asymmetries between them:

The universal of coordination: and has no denotational content; or means standard boolean join.

From this principle it follows that WS or effects should be regulated syntactically, which in the modification of Larson’s proposal is done by movement of the coordinator material. By contrast, and can show WS effects in contexts where Larson’s principles allow no coordinator displacement. Most notably, both…and constructions, unlike either…or coordinations, are ruled out in situations where and can clearly take wide
scope. For instance, sentence (8) has a reading where and “takes scope” over the
determiner, whereas a both...and construction as in (38) is totally out.

(38) *Both every man and woman arrived.

More generally, Larson observes that the syntactic distribution of both...and is more
restricted that the distribution of either...or, despite the apparent similarity between the
two constructions. One of Larson's examples is the contrast between (39) and (40).

(39) *Both Mary is going to school and holding down a job.
(40) Either Mary is going to school or holding down a job.

These points show that an account of WS and as stemming only from syntactic facts is
problematic. Rather, we need a semantic mechanism that can account for these effects
without any movement of the conjunction. The pointwise application mechanism
proposed in (16) is such a mechanism.

5. On two previous proposals

In this section I briefly discuss two previous approaches to the scope of coordination: the
type lifting approach and the DRT-based approach of Rooth and Partee to the problem
of wide scope or. I show that the type lifting approach does not account for the scopal
asymmetries between conjunction and disjunction. Rooth and Partee's proposal might be
necessary for certain complex examples with disjunction that are not accounted for
within the present framework. However, their approach does not describe wide scope
interpretations of and and the precise restrictions that govern its application with or
remain unknown.

5.1 Type lifting

A type lifting method to derive WS readings of coordinations was considered by Partee
and Rooth (1983), who attributed it to an unpublished manuscript by Robin Cooper. The
idea was further explored in Hendriks (1993). According to the type lifting rule of the
Lambek Calculus (Lambek 1958), any denotation \( x \) can be lifted to a function \( y \) whose
argument is any function that takes \( x \) as argument. For instance, since a common noun
can be an argument of a determiner, we can lift any common noun to a function that
takes determiners as arguments. In the case of the noun phrase every man and woman in
(8) this allows us to lift the denotation of the common noun man into the function that
assigns to any determiner \( D \) the quantifier \( D(\text{man'}) \). This is the function \( \lambda D.D(\text{man'}) \).
Similarly, the denotation of the common noun woman can be lifted to the function
\( \lambda D.D(\text{woman'}) \). These two functions can be coordinated as illustrated in (41) below.
Application of the resulting function to the determiner every leads to the desired WS and
reading of the noun phrase.
This technique, although successful in this particular case, has some general drawbacks when considering the data we have discussed:

1. The asymmetries between and and or with respect to alternately adverbials, as well as the cross-linguistic asymmetries between them, are not accounted for.
2. The scopal asymmetries between conjunction and disjunction are not expected either: the lifting procedure is independent of the identity of the coordinator, hence it predicts WS and WS or to be equally available.
3. Larson’s generalization on the correlations between WS or and the possible positions for either is not explained.

These points make clear that a system of type lifting, despite its elegance, does not make the necessary distinctions about the scope of coordination. It is hard to see how such a general mechanism can be restricted in order to capture the facts treated in the present paper.

5.2 Rooth and Partee’s approach to wide scope or

Rooth and Partee (1982) propose a semantics for WS or that is based on the DRT treatment of indefinites. Rooth and Partee (R&P) propose to analyze or coordinations using an introduction of a free variable that can be bound arbitrarily far away using the familiar DRT technique of unselective binding. To give a rough idea of this technique consider R&P’s representation of the WS or reading of (22):

\[ \exists P [\text{look}_P'(x',P) \wedge (P = \text{a maid'} \vee P = \text{a cook'})] \]

As R&P mention, a mechanism generating this representation would require highly complex syntactic procedures on surface structures that they do not spell out completely. However, I do believe that there is a correct insight in R&P’s observation on the similarity between disjunction and indefinites (in certain circumstances, at least). There might be an independent semantic/pragmatic factor affecting the scope of disjunction, which is additional to Larson’s syntactic/semantic generalization. To see the point, consider first R&P’s example (43) below. This sentence has arguably two readings. Under reading (43a) the constituent Sue is (missing a verb) in the consequent of the conditional is interpreted as Sue is swimming or dancing. This reading does not require that Mary and Sue are doing the same thing in cases where Mary is swimming or dancing: it might happen that Mary is swimming and Sue is dancing or vice versa. However, R&P claim that (43) has a reading like (43b), which requires that if Mary is swimming or dancing then Sue is doing whatever Mary is doing. R&P compare this reading to the notorious “donkey-pronoun” reading of sentences like (44).
(43) If Mary is swimming or dancing, then Sue is.
   a. If Mary is swimming or dancing then Sue is swimming or dancing.
   b. If Mary is swimming then Sue is swimming and if Mary is dancing then Sue is dancing.

(44) If Pedro owns a donkey, he beats it.

In the case of (43) it is quite hard to know if P&R’s ambiguity judgement is correct since the putative reading (43b) entails reading (43a). In such circumstances, it is not easy to decide if the reading in question needs to be semantically represented or if it is masked by the more general reading (43a).

I think a more robust test for the similarity between the scopal properties of disjunction and those of indefinites comes from island-insensitivity facts. Consider the following sentence.

(45) If Bill praises Mary or Sue then John will be happy.
   a. NS: If Bill praises Mary then John will be happy and if Bill praises Sue then John will be happy.
   b. WS: If Bill praises Mary then John will be happy or if Bill praises Sue then John will be happy.

Sentence (45) is quite clearly ambiguous. One reading, paraphrased in (45a), does not take John to have any particular preferences as for the girl that Bill will choose to praise. This is the “narrow scope” reading of the disjunction with respect to the conditional. However, suppose John likes one of the two girls and does not particularly like the other one. Suppose that John wants Bill to praise the girl he likes but he does not care what Bill has to say about the other girl. In this situation, the NS reading (45a) is false, but (45) clearly has a true interpretation, as paraphrased in (45b). This reading can be strengthened by adding to (45) a statement like, but I don’t know which one of the two girls John wants Bill to praise.

This fact shows an exception to Larson’s generalization: as Larson argues, either is expectedly ungrammatical when there is an island separating it from the disjunction. This is illustrated in (46). Nevertheless, as we have just established, a WS or beyond the conditional is possible in (45).

(46) *Either if Bill praises Mary or Sue then John will be happy.

This goes against a particular semantic proposal that Larson makes. Larson suggests that the semantic function of either and the null operator $O$ is to invoke existential quantification over the variable introduced by the corresponding disjunction. However, if this is the case, there is no clue as for the origin of the WS or interpretation of (45). If, on the other hand, we adopt R&P’s view that disjunctions behave like indefinites, then like indefinites, there should be no syntactic trigger for the existential scope of disjunctions. The analogy is clear by comparing (45) with (47), where a simple indefinite NP replaces the disjunction.

(47) If Bill praises some girl I know then John will be happy.
The sentence has a WS reading for the indefinite over the conditional, which can be paraphrased by: “there is some girl I know such that if Bill praises x then John will be happy”. Whatever mechanism is responsible for this WS interpretation of the indefinite in (47) (e.g. Reinhart’s (1997) choice function mechanism) may be claimed to be responsible also for the WS reading of the disjunction in (45) using R&P’s variable analysis. Of course, the drawback of this line is that it does not account at all for Larson’s generalization: it expects WS or, like WS readings of indefinites, to be insensitive to syntactic restrictions. This, as Larson observed, is not the case.

We are facing here a puzzling array of facts: why does Larson’s generalization on the scope of or hold in examples like (25)-(26) but not in (45)-(46)? While I do not have a complete answer to this question, it is plausible that the reason for such contrasts is differences in the availability of the mechanism that generates wide scope of indefinites. Thus, while the WS of the disjunction Mary or Sue in (45) can be treated using the choice function mechanism (or another mechanism for wide scope indefinites), this should no longer be the case in (26): the wide scope analysis of the noun phrase a maid or a cook using choice functions should generate only the WS de re reading of the indefinites, but not the WS reading of the disjunction with de dicto interpretations for the indefinites, which is the missing reading in (26). While I believe that the choice function mechanism of Reinhart (1997) and Winter (1997) can be used to generate these predictions, I must defer further analysis of this point to further research.

6. Conclusion

This paper addressed some problems in the analysis of the scope of coordination. We have seen cases where the boolean analysis alone cannot account for the semantics of coordination without additional assumptions. The main argument I tried to support is that wide scope effects with and coordinations motivate a modification of their classical semantic analysis in boolean frameworks, while wide scope effects with or result from a syntactic mechanism following Larson’s account. Wide scope and, as well as phenomena of null coordinations and modification by alternately, were treated by a semantic hypothesis that assigns and a zero meaning and uses the boolean meet operation as a universal covert process in natural language. Unlike the meaning of conjunctive coordinators, the meaning of disjunctive coordinators like or remains the classical join operator. The output of a syntactic mechanism à la Larson is interpreted using the same general pointwise application procedure that treats conjunctive coordinations. Thus, scopal asymmetries between conjunction and disjunction result from syntactic and lexical semantic differences between the two constructions, but the compositional interpretation of coordination is achieved by a uniform semantic mechanism.
